Nitrous oxide ( $\text{N}_2\text{O}$ ) is a major greenhouse gas that causes global warming and stratospheric ozone depletion. Ammonium nitrogen ( $\text{NH}_4^+$ -N) content is considered as a key factor affecting  $\text{N}_2\text{O}$  emissions because ammonium oxidation by nitrifying microorganisms is a major process of  $\text{N}_2\text{O}$  emissions. Exact effects of  $\text{NH}_4^+$ -N on  $\text{N}_2\text{O}$  emissions are less examined and even available findings are contradictory. Some studies found strongly positive linear correlations between  $\text{N}_2\text{O}$  emissions and  $\text{NH}_4^+$ -N content, while others stated reductions in  $\text{N}_2\text{O}$  emissions with increasing  $\text{NH}_4^+$ -N content. Therefore, the present study aimed at investigating effects of different  $\text{NH}_4^+$ -N contents on  $\text{N}_2\text{O}$  and carbon dioxide ( $\text{CO}_2$ ) emissions from manure compost amended soil.

Greenhouse soil was amended with two types of manure composts (Cattle compost, CC and Mixed compost was of cattle, poultry, and swine manure, MC) on 3% weight basis. The initial  $\text{NH}_4^+$ -N contents were adjusted at three levels of 160, 200, 400 mg/kg. The samples were aerobically incubated at 70% water holding capacity at 25°C for 42 days. Emissions of  $\text{N}_2\text{O}$  and  $\text{CO}_2$  (gas chromatography) and ammonium and nitrate N contents of soil were measured on days 0, 3, 7, 14, 21, 28, and 42.

The highest cumulative  $\text{N}_2\text{O}$  (200-420 mg kg<sup>-1</sup>) and  $\text{CO}_2$  (7-11 g kg<sup>-1</sup>) emissions were observed in MC amended soils at each  $\text{NH}_4^+$ -N level. This is probably due to high total N, low C/N, and high mineral N of MC. The MC amended treatments with 160 mg/kg  $\text{NH}_4^+$ -N content showed peak emissions on day 7. In all the other treatments,  $\text{N}_2\text{O}$  emissions peaked on day 3 indicating that the nitrification process was enhanced by the addition of  $\text{NH}_4^+$ -N. The cumulative  $\text{N}_2\text{O}$  and  $\text{CO}_2$  emissions in 400 mg/kg  $\text{NH}_4^+$ -N treatments were lower than those in 200 mg/kg  $\text{NH}_4^+$ -N treatments despite the addition of compost. Higher  $\text{NH}_4^+$ -N content would have suppressed the microbial activity probably due to enhanced osmotic effects. In both control and CC amended treatments, cumulative  $\text{N}_2\text{O}$  and  $\text{CO}_2$  emissions increased with  $\text{NH}_4^+$ -N contents from 160 to 200 mg/kg, whereas they decreased in 400 mg/kg  $\text{NH}_4^+$ -N treatments. The variation of  $\text{NO}_3^-$ -N content showed that the MC amended treatment with 160 mg/kg  $\text{NH}_4^+$ -N content was subjected to high denitrifying activity compared to the other treatments. With increasing  $\text{NH}_4^+$ -N content, the denitrifying activity seemed to decrease due to high osmotic potential. In conclusion, different types of compost have different amounts of  $\text{N}_2\text{O}$  and  $\text{CO}_2$  emissions at each  $\text{NH}_4^+$ -N content. More  $\text{NH}_4^+$ -N suppressed microbial activities due to osmotic stress and therefore lower  $\text{N}_2\text{O}$  and  $\text{CO}_2$  emissions were recorded. Content of  $\text{NH}_4^+$ -N can be a key factor in determination of  $\text{N}_2\text{O}$  emissions.
